# Introduction

*Hurricane Andrew damaged hundreds of homes in south Florida.*

In the early morning hours of August 24, 1992, Hurricane Andrew struck south Florida with high winds and heavy rains (Figure 1). Andrew destroyed tens of thousands of homes (Figure 2) and left 180,000 people homeless. The resulting property damage totaled over 30 billion dollars.

**Figure 1**  
Hurricane Andrew was a Category 4 hurricane with peak winds of over 140 mph.

## **WARNING**

The house elevation techniques described in this publication are appropriate only for houses **not** subject to the severe coastal flood hazards associated with high-velocity wave action from storms or seismic sources. See pages 2-2 through 2-4 for more information.

**Figure 2**  
Damage to houses  
and other buildings  
was severe.

The widespread destruction caused by Andrew was due primarily to high winds (Figure 3). However, flood waters contributed to the damage in low-lying coastal areas of central and southern Miami-Dade County (Figure 4).

**Figure 3**  
Wind damage.

**Figure 4**

In low-lying areas, wind and rain damage to interior finishes and furnishings was exacerbated by flood waters.

**DEFINITION**

In a **slab-on-grade** house, the floor of the house is formed by a concrete slab that sits directly on the ground.

In the repair and reconstruction efforts that followed Hurricane Andrew, owners of damaged houses had opportunities to modify their houses to protect them from future flood damage. One effective method of protecting a house from flooding is elevating the habitable areas of the house above the flood level.

Almost all single-family homes in Miami-Dade County are constructed with reinforced masonry block walls on a **slab-on-grade** foundation. Houses of this type are the most difficult to elevate for flood protection. This publication describes how homeowners in Miami-Dade County elevated their damaged slab-on-grade masonry houses following the devastating effects of Hurricane Andrew.

### DEFINITION

The **Federal Emergency Management Agency (FEMA)** is the independent Federal agency that administers the National Flood Insurance Program (NFIP).

Chapter 2 of this publication explains how the **Federal Emergency Management Agency (FEMA)** provided technical and regulatory guidance to Miami-Dade County homeowners concerning alternative house elevation techniques. Chapter 3 presents an overview of three common techniques appropriate for a variety of houses on different types of foundations. Chapter 4 uses eight illustrated case studies to demonstrate how Miami-Dade County homeowners used the three techniques to elevate their slab-on-grade houses. The benefits of elevating a floodprone house are summarized in Chapter 5.

For information about obtaining videotape and CD-ROM versions of this publication, refer to Chapter 6.

# Homeowner Options

*FEMA provided on-site guidance to homeowners concerning repair options compliant with the local floodplain management ordinance.*

## National Flood Insurance Program

The repair of damaged houses in floodprone areas of Miami-Dade County is governed by floodplain management regulations enacted by the county as a participant in the National Flood Insurance Program (NFIP). The NFIP is a Federal program that helps communities reduce flood risks and enables property owners and renters to buy flood insurance. The program is administered by FEMA.

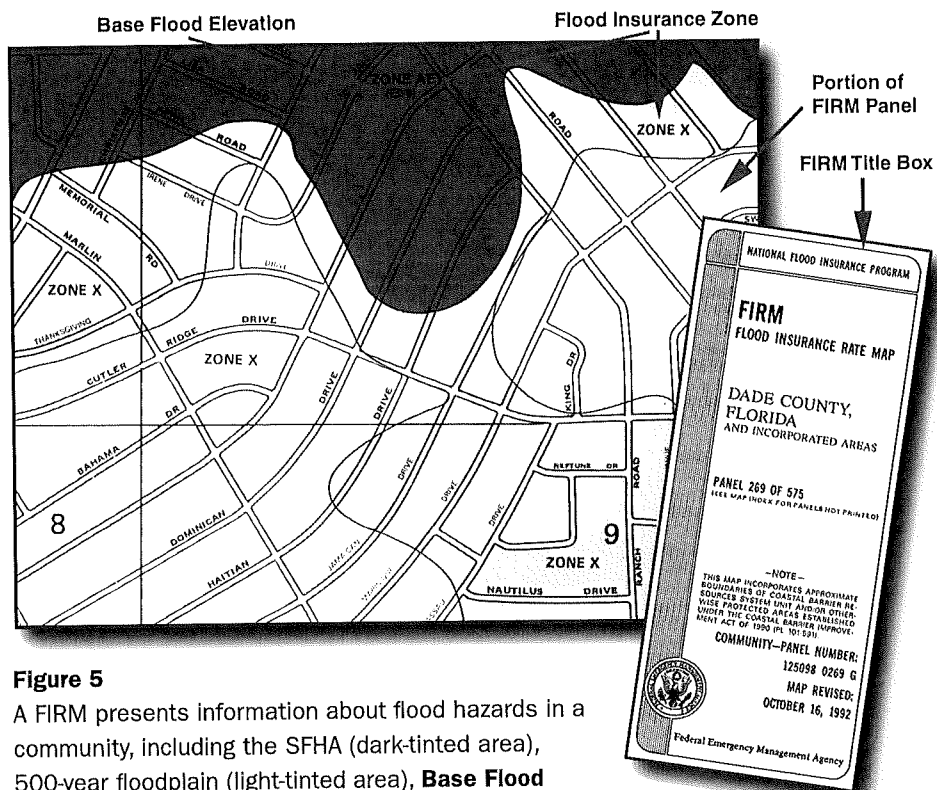

### DEFINITION

The **Special Flood Hazard Area (SFHA)**

is the area inundated by the flood that has a 1-percent probability of being equaled or exceeded during any given year. The NFIP regulations refer to this flood as the "base flood."

Communities participate in the NFIP by enacting and enforcing floodplain management regulations to reduce future flood risks. At a minimum, these regulations govern construction in the **Special Flood Hazard Areas (SFHAs)** shown on Flood Insurance Rate Maps (FIRMs) issued by FEMA (Figure 5).

**Figure 5**

A FIRM presents information about flood hazards in a community, including the SFHA (dark-tinted area), 500-year floodplain (light-tinted area), **Base Flood Elevations**, (BFEs) (number in parentheses), and flood insurance zones (AE and X in this example).

#### DEFINITION

The **Base Flood Elevation (BFE)** is the elevation of the flood that has a 1-percent probability of being equaled or exceeded in any given year. The NFIP regulations refer to this flood as the "base flood."

Note that the SFHA in the example in Figure 5 is designated Zone AE. This zone is only one of several applied to SFHAs under the NFIP, including V, VE, V1-V30, A, AE, A1-A30, AO, and AH. These zones indicate differences in the types and severity of flood hazards in SFHAs. For the purposes of this publication, it is sufficient to focus on the basic differences between the two main types of SFHA zones—V zones and A zones. The distinction is important because regulatory requirements associated with V zones and A zones differ significantly. As explained later in this chapter, these requirements affect the types of building elevation techniques that may be used under the NFIP.

V zones (VE, V1-V30, and V) identify Coastal High Hazard Areas, which are SFHAs subject to high-velocity wave action from storms or seismic sources. The hazards in V zones include not only inundation by flood waters, but also the impact of waves and waterborne debris and the effects of severe scour and erosion. In contrast, A zones identify SFHAs not within the Coastal High Hazard Area. Although A zones and V zones both identify areas at risk from the base flood, the severity of the flood hazard is less in A zones, primarily because high-velocity wave action either is not present or is less significant than in V zones. Consequently, wave and debris impact, erosion, and scour hazards are less severe in A zones.

A participating community must regulate three types of building construction in the SFHA (in both V zones and A zones):

- new construction
- substantial improvements to existing buildings
- repairs of substantially damaged buildings

For floodplain management purposes, the NFIP regulations, at Section 59.1 of the U.S. Code of Federal Regulations (CFR), define new construction, substantial improvement, and substantial damage as follows:

- **New construction** – structures for which the start of construction commenced on or after the effective date of a floodplain management regulation adopted by a community and includes any subsequent improvements to such structures.
- **Substantial improvement** – any reconstruction, rehabilitation, addition, or other improvement of a structure, the cost of which equals or exceeds 50 percent of the market value of the structure before the start of construction of the improvement.
- **Substantial damage** – damage of any origin sustained by a structure whereby the cost of restoring the structure to its before damaged condition would equal or exceed 50 percent of the market value of the structure before the damage occurred.

If a building is significantly damaged by **any** cause, not just by flooding, the community's floodplain administrator—who may or may not be the local building official—must determine whether the building is *substantially damaged*, as defined above. FEMA does not play a direct role in this determination. Rather, FEMA's role and that of the NFIP State Coordinator is to provide technical assistance to local officials who administer community ordinances that meet the NFIP minimum floodplain management requirements.

Each participating community must require that new residential buildings, substantially improved residential buildings, and substantially damaged residential buildings be elevated above the BFE so that the potential for future flood damage is reduced. The elevation techniques that may be used under the NFIP depend on whether the building to be elevated is in a V zone or an A zone.

In a V zone, the NFIP regulations require that the building be elevated on an open foundation (e.g., pilings, posts, piers) and that the bottom of the **lowest horizontal structural member** (e.g., floor support beam) be at or above the BFE. In other words, a building in a V zone may not be supported by continuous walls below the BFE. The basis for this requirement is that continuous walls, and therefore the building they support, are more susceptible to damage from the additional hazards present in V zones—wave impact, waterborne debris impact, scour, and erosion, as discussed previously.

**DEFINITION**

Under the NFIP regulations, the **lowest floor** of a house or other building is the lowest floor of the lowest enclosed area, including a basement.

In A zones, where flood hazards are less severe, buildings may be elevated either on an open foundation or on continuous foundation walls below the BFE (Figure 6). Regardless of the type of foundation used, A-zone buildings must be elevated so that the **lowest floor** is at or above the BFE, as shown in Figure 6. If continuous walls are used below the BFE, they must be equipped with openings that allow flood waters to flow into and out of the area enclosed by the walls (Figure 6). Allowing the entry and exit of flood waters ensures that water pressures will be the same on both sides of the walls and reduces the likelihood that water pressure will cause the walls to fail.

**Figure 6**

In a new, substantially improved, or substantially damaged building in an A zone, the elevation of the lowest floor must be at or above the BFE.

It is important to note that each of the elevation techniques described and illustrated in this publication depends on the use of continuous walls below the BFE. Therefore, under the NFIP regulations, these techniques may be used only for buildings in A zones, such as the eight case study buildings presented in Chapter 4.

## Technical and Regulatory Guidance from FEMA

In the aftermath of Hurricane Andrew, homeowners wanted to begin repairing their damaged houses as soon as possible. They needed immediate guidance concerning repair methods and the floodplain management requirements enforced by Miami-Dade County as a participant in the NFIP. To respond to these needs under the catastrophic conditions resulting from Hurricane Andrew, FEMA, in partnership with other Federal agencies, the State of Florida, and Miami-Dade County, established a Reconstruction Information Center (RIC) in the area where the greatest damage had occurred.

### NOTE

In major disasters, FEMA and the affected state will often open one or more Disaster Recovery Centers (DRCs). At a DRC, homeowners and other interested parties can obtain information about how to reduce future flood losses through hazard mitigation.

The RIC provided homeowners with engineering and architectural advice, guidance regarding floodplain management regulations, and information about financial assistance programs operated by FEMA and other agencies. These services were available to all homeowners but were especially valuable to owners of substantially damaged houses.

At the RIC, owners of substantially damaged houses in SFHAs learned that they had two options for complying with the requirement to elevate the lowest floor to or above the flood level:

1. Demolish the remnants of the house and build a new house on the same site with an elevated lowest floor, or
2. Repair the house and elevate the lowest floor as part of the repair process.

Owners of substantially damaged houses in SFHAs that remained structurally sound usually chose the second option—repairing the house and elevating the lowest floor. Depending on how the houses were constructed, their owners had a choice of up to three techniques for elevating the lowest floor (as illustrated on the following pages):

1. Extend the walls of the house upward and raise the lowest floor (Figure 7).
2. Convert the existing lower area of the house to non-habitable space and build a new second story for living space (Figure 8).
3. Lift the entire house, with the floor slab attached, and build a new foundation to elevate the house (Figure 9).

Chapter 3 presents an overview of the three techniques. Chapter 4 covers the techniques in detail and shows how they were used in the repair of eight substantially damaged houses in south Florida.

**Figure 7**

Technique 1 –  
Extend the walls of  
the house upward and  
raise the lowest floor.

County floodplain  
management  
requirements

# Overview of the Elevation Techniques

*Homeowners had a choice of three techniques for elevating their substantially damaged houses.*

## **Technique 1– Extend the Walls of the House Upward and Raise the Lowest Floor**

Technique 1 is appropriate for houses with concrete or masonry walls, but not for houses with other types of walls, such as those framed with wood studs, which would be more vulnerable to flood damage. This technique is usually appropriate when the depth of the base flood at the house is no more than 4 or 5 feet above grade. The elevation process begins with the temporary removal of the roof and roof framing, in a single piece if possible (Figure 10). This is commonly done with a crane. The roof is then stored on site so that it can be reinstalled later. The next step is to remove the windows and doors.

**Figure 10**  
The first step in Technique 1 is removing the roof.

After the roof, windows, and doors are removed, several courses of concrete block are added to the tops of the existing walls and to the bottoms of the window openings (Figure 11). A corresponding number of blocks are removed from the tops of the window openings so that the size of the windows will remain the same. In addition, although not shown in Figure 11, concrete bond beams are formed in place at the tops of the extended walls to provide structural reinforcement.

**Figure 11**

The tops of the walls and bottoms of the window openings are raised with concrete blocks.

Blocks are removed from the walls of the house at selected locations within 1 foot of the ground (Figure 12). The resulting openings will allow flood waters to flow into and out of the lower area of the house so that the water pressures on both sides of the walls will remain the same. The roof and windows are then replaced, and a new wood-frame floor is constructed above the flood level (Figure 13).

**Figure 12**  
Openings are created  
in the walls near the  
ground.

**Figure 13**  
A new wood-frame  
lowest floor is  
constructed above the  
flood level, and the  
roof, windows, and  
doors are reinstalled.

A homeowner who chooses Technique 1 may decide to build a new concrete slab floor instead of a wood floor (Figure 14). When this option is chosen, compacted fill dirt or gravel is placed on top of the old slab and the new slab floor is poured on top. Because the area below the new floor is filled with dirt or gravel, wall openings are not required.

**Figure 14**  
An alternative to building an elevated wood-frame floor is installing a new, elevated concrete slab floor on fill placed over the old slab.

### **Technique 2 – Convert the Existing Lower Area of the House to Non-Habitable Space and Build a New Second Story for Living Space**

When the depth of the base flood at the house is more than 4 or 5 feet above grade, the homeowner will usually find it more practical to add an entire second story to the house. The lower area of the house is then converted to non-habitable space that may be used only for parking, storage, or access to the upper story. Flood waters may still enter this non-habitable lower area. For this reason, Technique 2, like Technique 1, is appropriate for houses with concrete or masonry walls, but not houses with other types of walls.

As in Technique 1, the repairs begin with the temporary removal of the roof and roof framing (Figure 10). After the roof is removed, construction of the new second story begins. First, a new wood-frame floor is built on top of the existing lower-story walls. The second-story walls are framed with metal or wood studs and set in place on the floor (Figure 15).

**Figure 15**  
The new second-story floor and walls are built on top of the existing lower story.

Some homeowners prefer that the second story be constructed of masonry, but wood- or metal-framing is more common, primarily because it is lighter and less expensive. The roof is replaced, and blocks are removed from the walls to allow flood waters to enter and exit. Exterior sheathing is then added to the framed walls of the second story, the new windows are installed, and siding or stucco is applied to the sheathing (Figure 16).

**Figure 16**  
The new second-story walls are covered with siding or stucco.

**Technique 3 – Lift the Entire House, With the Floor Slab Attached, and Build a New Foundation To Elevate the House.**

Technique 3 can be used for houses with wood-frame or masonry walls and is appropriate for a wide range of flood levels. This technique is very different from Techniques 1 and 2. Here, the entire house, including its slab floor, is lifted above the flood level and new masonry foundation walls are built below it. The most common method of lifting the house is to place metal I-beams below the slab and raise the house with jacks.

First, trenches are dug to expose the foundation walls immediately below the slab. Holes are then cut in the foundation walls at intervals around the house, and tunnels are dug under the slab (Figure 17). Jacks are placed in the trenches and large I-beams are inserted through the tunnels and allowed to rest on the jacks. Smaller I-beams are then inserted through the tunnels at right angles to the larger beams and positioned on top of them. The smaller beams support the slab when the house is raised (Figure 18).

**Figure 17**  
Trenches and tunnels under the slab provide access for the jacks and I-beams that will lift the house.

**Figure 18**  
With I-beams and jacks in place, the house is ready to be lifted.

The house is then jacked up. When the jacks have extended as far as possible, the house must be supported temporarily while the jacks are raised. Both the house and the jacks are usually supported on “cribbing”—temporary piles of crisscrossed timbers (Figure 19). The jacks are then used to raise the house higher.

**Figure 19**  
The house is temporarily supported on cribbing.

This process is repeated until the house is raised to the desired height. The foundation walls are then extended upward with additional rows of concrete block (Figure 20). As in the previous techniques, openings are made in the walls within 1 foot of the ground so that flood waters will be able to flow into and out of the area below the elevated floor. The jacks and beams are removed, and the openings left around the beams are filled with blocks (Figure 21).
